ABSTRACT

**Objectives:** To describe and compare the initial clinical characteristics of a cohort of patients with suspected COVID-19 (confirmed, no COVID, and uncertain cases) managed by general practitioners (GPs); to assess whether 3-month persistent symptoms were more frequent among confirmed cases than among no-COVID cases; and to identify factors predictive of persistent symptoms and adverse outcomes among confirmed cases.

**Design and setting:** A comparative, prospective, multicentre cohort study in primary care, in the Paris region of France.

**Participants:** 521 patients aged  $\geq 18$  with suspected COVID-19 were enrolled between March and May 2020; people under 18 or with no suspicion of COVID-19 or institutionalized were excluded.

**Outcome measures:** Initial symptoms, COVID-19 status, persistent symptoms 3 months post-inclusion, and a composite criterion for potentially COVID-19-related events (hospitalization, death, emergency department visits).

**Results:** 516 patients were analyzed; 166 (32.2%) were classified into the “confirmed COVID” group, 180 (34.9%) into the “no-COVID” group and 170 (32.9%) in the “uncertain COVID” group. Confirmed cases had more persistent symptoms than no-COVID cases ( $P=0.09$ ), were more likely to have anosmia ( $P=0.047$ ) and other rare symptoms ( $P=0.071$ ); initial fever/feeling feverish and anosmia were independently associated with persistent symptoms. At 3 months, we observed 16 (9.8%) COVID-19 related hospitalizations, 3 (1.8%) intensive care unit admissions, 13 (37.1%) referrals to an emergency department, and no deaths. Age  $>70$  and/or at least one comorbidity (OR 6.53; 95% CI [1.13-37.84];  $P=0.036$ ), abnormalities in a lung examination (15.39 [1.61-146.77];  $P=0.057$ ) and two or more

systemic symptoms (38.61 [2.30-647.40];  $P=0.011$ ) were associated with the composite criterion.

**Conclusions:** Although most COVID-19 patients in primary care had mild disease with a benign course, almost 1 in 6 had persistent symptoms at 3 months. These symptoms were more frequent in the “confirmed COVID-19” group. Our findings need to be confirmed in a prospective study with longer follow-up.

### **Strengths and limitations of this study**

This work is one of the few French studies to have included solely patients in primary care early on in the first wave of the COVID-19 pandemic.

In contrast to most COVID-19 studies, this study featured a control group: “confirmed COVID-19” patients were compared with “no-COVID-19” and “uncertain COVID-19” patients.

This prospective cohort study was carried out over a short time frame in several primary care health centres; some results might be extrapolable to other settings.

Early on in the pandemic, COVID-19 RT-PCR tests were not widely available. Consequently, COVID-19 status (or not) was not confirmed in all patients.

Individuals under the age of 18 and those living in an institution were not included in the study.

**BACKGROUND**

The first wave of COVID-19 in France prompted a lockdown from mid-March to mid-May 2020. General practitioners (GPs) were in the front line [1]; they referred severe cases to hospital and managed less severe cases [2]. Early on in the epidemic, researchers sought to describe the COVID-19 patients’ demographic and clinical characteristics and their course of disease. However, these studies were fully [3-8] or partly [9] conducted in hospital. The most frequently reported initial signs were fever, cough, and dyspnoea [3]. Anosmia and ageusia were also prevalent, and their concomitant presence was quite specific for a SARS-CoV-2 infection [10-12]. At the time when our study data were collected, some researchers had highlighted “long COVID-19” as an entity with some or all the following symptoms 3 to 12 months after disease onset [8,13,14]: persistent asthenia, headache, dyspnoea, sleep difficulties, anxiety or depression, and anosmia [13,14]. The significance of these symptoms is subject to debate, particularly since the literature data were somewhat contradictory; however, some researchers have suggested that these symptoms are correlated with the severity of the initial disease [8] and the number of initial symptoms [15]. Most of these studies of “long COVID-19” estimated the frequency of persistent symptoms or adverse outcomes in hospital cohorts of patients with a confirmed diagnosis of COVID-19 but lacked a control group [3,4,7-8]. Hence, these studies were not representative of patients in primary care – even though most COVID-19 cases are diagnosed by GPs [2]. Therefore, the objectives of the present study were to (i) describe and compare the initial clinical characteristics of a cohort of patients with suspected COVID-19 managed by GPs (confirmed cases, no-COVID cases, and uncertain cases); (ii) determine whether persistent symptoms at 3 months were more frequent among confirmed cases than among no-COVID cases; and (iii) identify factors predictive of persistent symptoms and adverse outcomes among confirmed cases.

## METHODS

### Study design

This multicentre, prospective cohort study was conducted in four counties in the Paris region: Val-de-Marne, Seine-et-Marne, Essonne, and Seine-Saint-Denis. Forty-four GPs were recruited from multiprofessional primary care practices affiliated with the Faculty of Health at Université Paris-Est Créteil (Créteil, France), because some of the GPs tutored the university's medical students. The GPs' characteristics are summarized in the Online Supplement 1 Table S1.

### Population

During the first wave's lockdown period, we prospectively included all consecutive adult patients who consulted one of the participating GPs for a suspected COVID-19 infection. The exclusion criteria were age under 18, no suspicion of COVID-19, and residence in an institution. The first patient was included on March 6<sup>th</sup>, 2020, and the last was included on May 12<sup>th</sup>, 2020. Patients were followed up for three months, and study data were extracted on October 22<sup>nd</sup>, 2020.

### Data sources

The patients' data were extracted from the GPs' electronic medical records. The clinical criteria for a diagnosis of COVID-19 were left to the GP's discretion. Patients were followed up as usual by their GP, and all consultations with healthcare professionals and/or hospital visits were registered. Three months after inclusion, the GP phoned or visited patients to collect data on persistent symptoms or recovery. For confirmed cases, they also looked for COVID-19-related hospital admissions, referrals to an emergency department, admissions to

an intensive care unit, and deaths. These data were completed with information from hospital discharge reports, if available.

**COVID-19 status**

The GPs prescribed SARS-CoV-2 serology and/or RT-PCR tests and/or a CT scan of the chest, in line with the French national guidelines [16-20]. During the first wave of COVID-19 (mid-March to mid-May 2020), RT-PCR and serology tests were not widely available. An RT-PCR test was recommended for patients with severity criteria and/or with comorbidities, and for healthcare professionals [16-17]. The French national guidelines recommended a CT scan if the patient had trouble breathing, in order to assess the extent of any lung damage and to have a reference examination [20]. Serology tests became available from May 2020 and were prescribed *a posteriori* to (i) patients with compatible symptoms and who had not had an RT-PCR test and (ii) patients with a negative RT-PCR test [17-18].

Each patient’s COVID-19 status was classified as “confirmed COVID”, “no-COVID”, or “uncertain COVID”. Confirmed COVID status was defined as a positive RT-PCR and/or serology test, and/or a chest CT result suggestive of COVID-19. “No-COVID” status was defined as both a negative RT-PCR test and a negative serology test, a negative RT-PCR test in the absence of a positive serology test or a positive chest CT, or a negative serology test in the absence of a positive RT-PCR test or a positive chest CT. “Uncertain COVID” status was defined as the presence of suggestive symptoms and the absence of both RT-PCR and serology test and chest CT results.

**Outcomes**

We considered the two following outcomes: the persistence of symptoms three months after study inclusion (as assessed by the GP), and (for confirmed cases only) adverse outcomes

defined by a composite criterion that included COVID-19-related hospital admissions, referral to an emergency department, intensive care unit admissions, and deaths. The relationship with COVID-19 was determined from hospital records.

### **Potential factors predictive of 3-month persistent symptoms and adverse outcomes**

Among confirmed cases, the following variables (Table 1) collected at the initial consultation were considered as potentially predictive factors for persistent symptoms and adverse outcomes: demographic characteristics (age, sex, being a caregiver), smoking, obesity, comorbidities, initial COVID-19 symptoms, the number of symptoms, systemic symptoms (i.e., fever, headache, asthenia, and skin symptoms), ENT symptoms, and data from an initial clinical examination.

### **Statistical analysis**

Qualitative variables were described as the number (percentage), and quantitative variables were described as the median [interquartile range (IQR)] or tertile values, as appropriate. Univariate analyses used the chi-2 test, the Fisher's test or the Kruskal-Wallis test, as appropriate. Given the hierarchical nature of the data (level 1: the patient; level 2: the GP), we used multilevel logistic models [21] to estimate univariate and multivariate odds ratios (ORs) and their 95% confidence intervals (CIs).

The distribution of the patient initial characteristics was compared across the three groups (confirmed, no-COVID, and uncertain). When the *P*-value was  $\leq 0.15$ , we used age-adjusted multilevel logistic models to perform post-hoc pairwise comparisons for confirmed cases vs. no-COVID cases on one hand, and between confirmed cases and uncertain cases on the other. Next, we compared the prevalence of persistent symptoms in the confirmed vs. no-COVID groups. To assess predictive factors for 3-month persistent symptoms and adverse outcomes

among the COVID confirmed cases, we compared the groups with vs. without persistent symptoms and with vs. without adverse outcomes, in univariate analyses. Factors with  $P<0.15$  in the univariable analysis were considered for inclusion in multivariable logistic analyses after the assessment of confounders and interactions in bivariate models. As “older age” and “at least one comorbidity” were highly correlated, we built the following composite variable: “age>70 and/or at least one comorbidity”. Lastly, in a sensitivity analysis, patients with both anosmia and ageusia but no test results were moved from the “uncertain COVID-19” group to the “confirmed” group, and similar analyses were performed. All tests were two-sided, and the threshold for statistical significance was set to  $P\leq0.05$ . We used the false discovery rate method for post-hoc analyses. All analyses were performed with Stata software (version 14.2, StataCorp LLC, College Station, TX, USA).

**Ethics**

All patients received an information sheet and gave their verbal consent to participation. The study database was registered with the French National Data Protection Commission (reference: 2211627 v0). The study protocol was approved by an independent ethics committee (*Comité de Protection des Personnes Est IV* (Strasbourg, France); reference: IDRCB 2020-A01693-36).

**RESULTS**

***Study population***

During the study period, 521 patients were included. Of these, 516 were analysed: 166 (32.2%) were classified as “confirmed COVID”, 180 (34.9%) were classified as “no-COVID”, and 170 (32.9%) were classified as “uncertain COVID” (Figure 1).

### ***Characteristics of the population, and intergroup comparisons***

In the overall population, median [IQR] age was 43 y [33-56], 62.2% were female, 12% were caregivers, and 40.7% had at least one comorbidity (Table 1). The three groups differed significantly with regard to the following initial characteristics: age, being a caregiver, having been in contact with a positive case, having at least one comorbidity, fever or feeling feverish, having muscle ache, chest pain, dyspnoea, a sore throat, anosmia, agueusia, diarrhoea, and the number of systemic symptoms.

Relative to the no-COVID group, confirmed cases were significantly older and were more likely to be caregivers, to have been in contact with a confirmed case of COVID-19, and to have had anosmia or agueusia. A non-significant trend towards an association with a higher number of systemic symptoms was also observed. In contrast, chest pain and sore throat were less frequent in the “confirmed case” group.

Relative to the uncertain COVID-19 group, confirmed cases were significantly older and were more likely to be caregiver, to have been in contact with a confirmed case of COVID-19, to have had fever or feeling feverish, muscle ache, anosmia, agueusia, diarrhoea and more than two systemic symptoms. In contrast, they were less likely to be male.

### ***Three-month persistent symptoms in the “confirmed COVID” and “no-COVID” groups***

Overall, the percentage of three-month persistent symptoms was higher in the confirmed COVID group than in the no-COVID group, although the difference was not statistically significant ( $P=0.090$ ) (Table 2). The confirmed COVID group was more likely to have persistent anosmia (OR=8.51; 95% CI [1.03-70.43]) and other miscellaneous symptoms (deep vein thrombosis, alopecia, palpitations, myalgia, feeling feverish, and memory impairments) (OR=7.02; 95% CI [0.84-58.29]). Similar results were found in the sensitivity analysis (Table 2).

**Predictive factors for 3-month persistent symptoms and adverse outcomes in confirmed COVID cases**

In a univariate analysis, the factors associated with 3-month persistent symptoms were fever or feeling feverish and anosmia (Table 3). In a multivariate analysis, fever and anosmia were independently associated with 3-month persistent symptoms. Similar results were found in the sensitivity analysis ( $OR_{\text{fever}}=8.49$ ; 95% CI [1.34-53.83];  $P=0.023$  and  $OR_{\text{anosmia}}=4.24$  95%; 95% CI [0.99-18.23];  $P=0.052$ ).

Among the confirmed cases, we observed 16 (9.8%) COVID-19 related hospitalizations, 3 (1.8%) admissions to an intensive care unit, 13 (37.1%) referrals to an emergency department, and no deaths. In a univariate analysis, patients with 3-month adverse outcomes were older, and more likely to have at least one comorbidity (hypertension, dyslipidaemia, diabetes, and cardiovascular disease), fever or feeling feverish, and a higher number of systemic symptoms (Table 4). A trend was observed for abnormalities in a lung clinical examination. In a multivariate analysis, the composite variable “age >70 and/or at least one comorbidity”, abnormalities in a lung clinical examination and two or more systemic symptoms were independently associated with 3-month adverse outcomes (Table 4). Similar results were found in the sensitivity analysis ( $OR_{\text{fever}}=6.72$ ; 95% CI [1.24-36.54];  $P=0.027$ ;  $OR_{\geq 2 \text{ systemic symptoms}}=44.52$ ; 95% CI [2.67-741.89];  $P=0.008$ ; and  $OR_{\text{abnormalities in a lung examination}}=17.58$ ; 95% CI [1.80-171.63];  $P=0.047$ ).

**DISCUSSION**

**Principal findings**

During the first wave of COVID-19 in France, 32.2% of the patients with suspected COVID-19 were classified as “confirmed COVID” cases, 34.9% were classified as “no-COVID”

cases, and 32.9% were classified as “uncertain COVID” cases. The clinical course was mainly benign, although the hospital admission rate (with no deaths) was 9.8% in the “confirmed COVID” group. In the latter group, the variable “age >70 and/or at least one comorbidity”, abnormalities in a lung examination, and two or more systemic symptoms were independently associated with 3-month hospital admission and referral to an emergency department. Moreover, “confirmed COVID-19” patients tended to have more persistent symptoms at 3 months - mainly anosmia and “other persistent symptoms”. Fever or feeling feverish, and anosmia were independently associated with the persistence of symptoms.

### **Strengths and weaknesses of the study**

This is one of the few studies to have included solely patients consulting in general practice; most longitudinal studies of COVID-19 patients assessed hospital-based or mixed cohorts. Moreover, our assessment of a prospective multicentre cohort recruited at different primary care health centres means that our results can be more readily extrapolated on the local or regional level. Another study strength was our comparison of “confirmed COVID”, “no-COVID” and “uncertain COVID” groups; this provided a more accurate comparison of the initial and subsequent signs and symptoms of COVID-19. The “no COVID” group was particularly relevant for comparing the prevalence of persistent symptoms because it probably comprised patients with other viral diseases.

However, our study had some limitations. Selection bias might have been present because the RT-PCR test was only initially recommended for patients with severity criteria and/or with comorbidities, and for healthcare professionals. This may explain some of the demographic characteristics of confirmed cases. However, this bias was limited by the prescription of serology tests *a posteriori* to patients with compatible symptoms and who had not had an RT-PCR test and to patients with a negative RT-PCR test. We did not include

under-18 patients and institutionalized patients. The study was limited to the greater Paris region and so might not be representative of the French population as a whole. Moreover, the groups' size might have led to a lack of statistical power. Lastly, only COVID-related hospital admissions were recorded; it would have been useful to collect data on the symptom burden associated with all-cause hospital admissions.

**Comparison with other studies**

The demographic characteristics of our COVID-19 patients consulting in general practice were similar to those in the literature, particularly with regard to the mean age (43 in our study and in Yordanov et al.'s study [22]), the proportion of caregivers [23-24], and the most prevalent comorbidities (hypertension, and diabetes) [20]. Several studies of ambulatory patients have shown that systemic symptoms (including asthenia, fever, cough, myalgia, and headaches) were frequent [4,25-27]. Anosmia and ageusia were also frequent and appeared later in the course of disease. Some experts consider that the anosmia-ageusia combination is specific for COVID-19 [12]. Digestive tract symptoms were less frequent [4,6,28-30]. Our patients also varied with regard to the signs in the GPs' clinical examination (including abnormalities in a lung examination), as found in systematic reviews [12,31]. In line with our results, most studies of outpatients have found that the course of the disease is benign and that hospital admission is not required [17,22,23]. As found in the present research, literature data have shown that a higher frequency of negative outcomes (hospital admission and death) is associated with older age [32-33] and with comorbidities like cardiovascular disease and diabetes [22,33-34]. In contrast to another study, we did not find an association with male sex [35]. However, no other studies have found that more than two systemic symptoms at the initial GP visit and abnormalities in a lung examination are predictive of an adverse outcome.

These present findings and the literature data [12,31] highlight the need for a clinical consultation with the GP.

It appears that COVID-19 is a relapsing-remitting disease from which patients recover at different rates [36]. Here, we observed a non-significant trend toward a greater prevalence of persistent symptoms at 3 months in the “confirmed COVID” group (15.7%), vs. the no-COVID group (9.6%). This finding is in line with the results of a UK study in which 13.7% of outpatients had symptoms that persisted for at least 12 weeks [36]. However, the association remained significant in our “confirmed COVID” group for anosmia and “other symptoms” (i.e. deep vein thrombosis, alopecia, palpitations, feeling feverish, and memory impairments), as also reported elsewhere [37]. A recent, large cohort study suggested that self-reported infection was positively associated with persistent physical symptoms, whereas a positive serology test result for SARS-COV-2 was positively associated only with persistent anosmia [13]. Furthermore, it appears that one of the factors determining the presence of persistent symptoms in our COVID patients was the presence of fever during the initial GP visit. This association with fever has only previously been found in one study of elderly people [38] but not in other studies [39].

In our study, a comparison at 3 months showed that some persistent symptoms (asthenia, cough, chest pain, and dyspnoea) were not significantly more frequent in the “confirmed COVID” group - suggesting they were not specific for “long COVID-19”. Asthenia and dyspnoea were the two most common persistent symptoms in hospitalized and non-hospitalized patients [40]. However, we observed asthenia and dyspnoea respectively in around only 4% and 3% of our “confirmed COVID” patients, and with much the same frequency as in no COVID-19 patients (4.5% and 4.5%, respectively). Outpatient studies with a control group found the presence of persistent symptoms up to 10 [41] and 12 months [42] after mild COVID-19, with miscellaneous symptoms: asthenia, headaches, smell and

taste disorders, dyspnoea, memory disorders, insomnia, and difficulty concentrating [41-42].

The French health authorities also included neurological, cardiothoracic and sensory disorders in the list of persistent symptoms [43].

The results of these “long COVID-19” studies are relatively disparate and appear to show that this entity is non-specific because of the multisymptomatic, fluctuating nature of the clinical manifestations [43].

**Implications for clinicians and policymakers**

It is important to provide GPs with primary-care-specific data that enable them to optimize patient management. GPs have an essential role in combating the pandemic [44] and diagnose most patients with COVID-19 [2]. Identifying prognostic factors and examining patients for clinical abnormalities could help to detect patients at risk, set up follow-up procedures, and anticipate possible worsening [2,45]. These strategies might be needed in France, with a view to enabling primary care to withstand future health emergencies and pandemics, as has been mentioned in Australia, New Zealand, Canada, the Netherlands, the UK, and the US [46].

The trend towards more frequent persistent symptoms in patients with COVID-19 (more specifically, anosmia and “other symptoms”) suggests that follow-up by the GP should take account of the disease’s impact on quality of life, overall health and life context via a patient-centred approach [47].

**Unanswered questions and future research**

Our findings (notably concerning persistent symptoms) need to be confirmed in the longer term and in other patient populations (e.g. institutionalized people, children, and adolescents). Our study was partly based on electronic medical records and showed that

primary care can provide important public health data. This work could be expanded with patient surveys and GP interviews, so as to combine real-time data on patients' symptoms and adverse outcomes with patient responses to public health messaging and information on the GPs' adaptive coping mechanisms [46].

## CONCLUSIONS

Cases of COVID-19 seen in primary care have an essentially benign course. However, age >70 and/or at least one comorbidity, abnormalities in a lung examination, and a higher number of systemic symptoms were associated with hospital admission and referral to an emergency department. Our results reinforce the need for a face-to-face medical consultation by the GP to identify patients at risk of severe disease. Almost 1 in 6 COVID-19 patients had persistent symptoms at 3 months - emphasizing the need for an overall, patient-centred approach. This frequency of persistent symptoms tended to be higher in COVID-19 patients than in no-COVID-19 cases. Anosmia and a group of rarer symptoms were more prevalent in the "confirmed COVID" group. Asthenia, chest pain, cough, and dyspnoea were also present in the other groups and might not be specific for a possible "long COVID-19". Our findings in primary care need to be confirmed in prospective studies with a longer follow-up period.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	1
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	2-3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	4
Objectives	3	State specific objectives, including any prespecified hypotheses	4
Methods			
Study design	4	Present key elements of study design early in the paper	5
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	5-6
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	5-7
		(b) For matched studies, give matching criteria and number of exposed and unexposed	
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	6-7
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	6-7
Bias	9	Describe any efforts to address potential sources of bias	7-8
Study size	10	Explain how the study size was arrived at	5
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	7-8
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	7-8
		(b) Describe any methods used to examine subgroups and interactions	7-8
		(c) Explain how missing data were addressed	Tables
		(d) If applicable, explain how loss to follow-up was addressed	Figure 1
		(e) Describe any sensitivity analyses	8
Results			

Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed	8
		(b) Give reasons for non-participation at each stage	Figure 1
		(c) Consider use of a flow diagram	25
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders	9
		(b) Indicate number of participants with missing data for each variable of interest	
		(c) Summarise follow-up time (eg, average and total amount)	5
Outcome data	15*	Report numbers of outcome events or summary measures over time	
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included	9-10
		(b) Report category boundaries when continuous variables were categorized	Tables
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period	NA
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses	9-10
<b>Discussion</b>			
Key results	18	Summarise key results with reference to study objectives	10-11
<b>Limitations</b>			
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence	12-14
Generalisability	21	Discuss the generalisability (external validity) of the study results	14
<b>Other information</b>			
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based	16

\*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

**Note:** An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). ABSTRACT

**Objectives:** To describe and compare the initial clinical characteristics of a cohort of patients with suspected COVID-19 managed by general practitioners (GPs); to assess whether 3-month persistent symptoms were more frequent among confirmed cases than among no-COVID cases; and to identify factors predictive of persistent symptoms and adverse outcomes among confirmed cases.

**Design and setting:** A comparative, prospective, multicentre cohort study in primary care, in the Paris region of France.

**Participants:** 521 patients aged  $\geq 18$  with suspected COVID-19 were enrolled between March and May 2020.

**Outcome measures:** Initial symptoms, COVID-19 status, persistent symptoms 3 months post-inclusion, and a composite criterion for potentially COVID-19-related events (hospitalization, death, emergency department visits). The final COVID-19 status (“confirmed”, “no-COVID”, and “uncertain” cases) was determined by the GP after the receipt of the lab test results.

**Results:** 516 patients were analyzed; 166 (32.2%) were classified into the “confirmed COVID” group, 180 (34.9%) into the “no-COVID” group and 170 (32.9%) in the “uncertain COVID” group. Confirmed cases were more likely to have persistent symptoms than no-COVID cases ( $P=0.09$ ); initial fever/feeling feverish and anosmia were independently associated with persistent symptoms. At 3 months, we observed 16 (9.8%) COVID-19-related hospital admissions, 3 (1.8%) intensive care unit admissions, 13 (37.1%) referrals to an emergency department, and no deaths. Age  $>70$  and/or at least one comorbidity (OR 6.53; 95% CI [1.13-37.84];  $P=0.036$ ), abnormalities in a lung examination (15.39 [1.61-146.77];

$P=0.057$ ) and two or more systemic symptoms (38.61 [2.30-647.40];  $P=0.011$ ) were associated with the composite criterion.

**Conclusions:** Although most COVID-19 patients in primary care had mild disease with a benign course, almost 1 in 6 had persistent symptoms at 3 months. These symptoms were more frequent in the “confirmed COVID” group. Our findings need to be confirmed in a prospective study with longer follow-up.

**Keywords:** COVID-19, signs and symptoms, cohort studies, risk factors, general practice

### Strengths and limitations of this study

- This work is one of the few French studies to have included solely patients managed in primary care early on in the first wave of the COVID-19 pandemic.
- In contrast to most research on COVID-19, our study featured a control group (a “confirmed COVID” group, which was compared with “no-COVID” and “uncertain COVID” groups).
- The large number of primary care centres involved in the study suggests that our results can be extrapolated to the local and regional levels.
- Early on in the pandemic, COVID-19 RT-PCR tests were not widely available; COVID-19 status was not therefore confirmed in all patients.
- The small size of some subgroups (e.g. the subgroup of patients with persistent symptoms) might have led to a lack of statistical power and thus prevented us from drawing formal conclusions in that respect.

**BACKGROUND**

The first wave of COVID-19 in France prompted a lockdown from mid-March to mid-May 2020. General practitioners (GPs) were in the front line [1]; they referred severe cases to hospital and managed less severe cases [2]. Early on in the epidemic, researchers sought to describe the COVID-19 patients’ demographic and clinical characteristics and their course of disease. However, these studies were fully [3-8] or partly [9] conducted in hospital. The most frequently reported initial signs were fever, cough, and dyspnoea [3]. Anosmia and ageusia were also prevalent, and their concomitant presence was quite specific for a SARS-CoV-2 infection [10-12]. At the time when our study data were collected, some researchers had highlighted “long COVID-19” as an entity with some or all the following symptoms 3 to 12 months after disease onset [8,13,14]: persistent asthenia, headache, dyspnoea, sleep difficulties, anxiety or depression, and anosmia [13,14]. The significance of these symptoms is subject to debate, particularly since the literature data were somewhat contradictory; however, some researchers have suggested that these symptoms are correlated with the severity of the initial disease [8] and the number of initial symptoms [15]. Most of these studies of “long COVID-19” estimated the frequency of persistent symptoms or adverse outcomes in hospital cohorts of patients with a confirmed diagnosis of COVID-19 but lacked a control group [3,4,7-8]. Hence, these studies were not representative of patients in primary care – even though most COVID-19 cases are diagnosed by GPs [2]. Therefore, the objectives of the present study were to (i) describe and compare the initial clinical characteristics of a cohort of patients with suspected COVID-19 managed by GPs and whose COVID-19 status (“confirmed”, “no-COVID”, and “uncertain” cases) was determined by the GP after he/she had received the lab test results; (ii) determine whether persistent symptoms at 3 months were more frequent among confirmed cases than among no-COVID cases; and (iii) identify factors predictive of persistent symptoms and adverse outcomes among confirmed cases.

## METHODS

### Patient and public involvement

All patients received an information sheet and gave their verbal consent to participation. They were not involved in the study design, conduct or reporting or the plans for dissemination.

### Study design

This multicentre, prospective cohort study was conducted in four counties in the Paris region: Val-de-Marne, Seine-et-Marne, Essonne, and Seine-Saint-Denis. Forty-four GPs were recruited from multiprofessional primary care practices affiliated with the Faculty of Health at Université Paris-Est Créteil (Créteil, France), because some of the GPs tutored the university's medical students. The GPs' characteristics are summarized in the Online Supplement 1 Table S1.

### Population

During the first wave's lockdown period, we prospectively included all consecutive adult patients who consulted one of the participating GPs for a suspected COVID-19 infection. The exclusion criteria were age under 18, no suspicion of COVID-19, and residence in an institution. The first patient was included on March 6<sup>th</sup>, 2020, and the last was included on May 12<sup>th</sup>, 2020. Patients were followed up for three months, and study data were extracted on October 22<sup>nd</sup>, 2020.

### Data sources

The patients' data were extracted from the GPs' electronic medical records. The clinical criteria for a diagnosis of COVID-19 were left to the GP's discretion. Patients were followed

up as usual by their GP, and all consultations with healthcare professionals and/or hospital visits were registered. Three months after inclusion, the GP phoned or visited patients to collect data on persistent symptoms or recovery. For confirmed cases, they also looked for COVID-19-related hospital admissions, referrals to an emergency department, admissions to an intensive care unit, and deaths. These data were completed with information from hospital discharge reports, if available.

**COVID-19 status**

The GPs prescribed SARS-CoV-2 serology and/or RT-PCR tests and/or a CT scan of the chest, in line with the French national guidelines [16-20]. During the first wave of COVID-19 (mid-March to mid-May 2020), RT-PCR and serology tests were not widely available. An RT-PCR test was recommended for patients with severity criteria and/or with comorbidities, and for healthcare professionals [16-17]. The French national guidelines recommended a CT scan if the patient had trouble breathing, in order to assess the extent of any lung damage and to have a reference examination [20]. Serology tests became available from May 2020 and were prescribed *a posteriori* to (i) patients with compatible symptoms and who had not had an RT-PCR test and (ii) patients with a negative RT-PCR test [17-18].

The patient’s COVID-19 status was ultimately classified by the GP as “confirmed COVID”, “no-COVID”, or “uncertain COVID” after he/she had received the lab test results. Confirmed COVID status was defined as a positive RT-PCR and/or serology test, and/or a chest CT result suggestive of COVID-19. “No-COVID” status was defined as both a negative RT-PCR test and a negative serology test, a negative RT-PCR test in the absence of a positive serology test or a positive chest CT, or a negative serology test in the absence of a positive RT-PCR test or a positive chest CT. “Uncertain COVID” status was defined as the presence of suggestive symptoms and the absence of both RT-PCR and serology test and chest CT results.

## Outcomes

We considered the two following outcomes: the persistence of symptoms three months after study inclusion (as assessed by the GP), and (for confirmed cases only) adverse outcomes defined by a composite criterion that included COVID-19-related hospital admissions, referral to an emergency department, intensive care unit admissions, and deaths. The relationship with COVID-19 was determined from hospital records. The GP identified and recorded the patient's persistent symptoms (if any), according to his/her usual clinical practice. We asked the GPs three questions: "*Do you consider that the patient has been cured?*", "*If not, which symptoms persisted?*", and "*Do you attribute those symptoms to the initial disease?*". Persistent symptoms (if any) were not rated on a scale or using a questionnaire.

## Potential factors predictive of 3-month persistent symptoms and adverse outcomes

Among confirmed cases, the following variables (Appendix 1) collected at the initial consultation were considered as potentially predictive factors for persistent symptoms and adverse outcomes: demographic characteristics (age, sex, being a caregiver), smoking, obesity, comorbidities, initial COVID-19 symptoms, the number of symptoms, systemic symptoms (i.e., fever, headache, asthenia, and skin symptoms), ENT symptoms, and data from an initial clinical examination.

## Statistical analysis

Qualitative variables were described as the number (percentage), and quantitative variables were described as the median [interquartile range (IQR)] or tertile values, as appropriate. Univariate analyses used the chi-2 test, the Fisher's test or the Kruskal-Wallis test, as appropriate. Given the hierarchical nature of the data (level 1: the patient; level 2: the GP),

we used multilevel logistic models [21] to estimate univariate and multivariate odds ratios (ORs) and their 95% confidence intervals (CIs).

The distribution of the patient initial characteristics was compared across the three groups (confirmed, no-COVID, and uncertain). When the  $P$ -value was  $\leq 0.15$ , we used age-adjusted multilevel logistic models to perform post-hoc pairwise comparisons for confirmed cases vs. no-COVID cases on one hand, and between confirmed cases and uncertain cases on the other. Next, we compared the prevalence of persistent symptoms in the confirmed vs. no-COVID groups. To assess predictive factors for 3-month persistent symptoms and adverse outcomes among the COVID confirmed cases, we compared the groups with vs. without persistent symptoms and with vs. without adverse outcomes, in univariate analyses. Factors with  $P < 0.15$  in the univariable analysis were considered for inclusion in multivariable multilevel logistic analyses after the assessment of confounders and interactions in bivariate models. As “older age” and “at least one comorbidity” were highly correlated, we built the following composite variable: “age  $> 70$  and/or at least one comorbidity”. Lastly, in a sensitivity analysis, patients with both anosmia and ageusia but no test results were moved from the “uncertain COVID” group to the “confirmed COVID” group, and similar analyses were performed. All tests were two-sided, and the threshold for statistical significance was set to  $P \leq 0.05$ . We used the false discovery rate method for post-hoc analyses. All analyses were performed with Stata software (version 14.2, StataCorp LLC, College Station, TX, USA).

**Ethics**

The study database was registered with the French National Data Protection Commission (reference: 2211627 v0). The study protocol was approved by an independent ethics committee (*Comité de Protection des Personnes Est IV* (Strasbourg, France); reference: IDRCB 2020-A01693-36).

## RESULTS

### *Study population*

During the study period, 521 patients were included. Of these, 516 were analysed: 166 (32.2%) were classified as “confirmed COVID”, 180 (34.9%) were classified as “no-COVID”, and 170 (32.9%) were classified as “uncertain COVID” (Figure 1). The characteristics of the groups’ test results and disease classifications are summarized in Supplementary 2 Table S2.

### *Characteristics of the population, and intergroup comparisons*

In the overall population, median [IQR] age was 43 y [33-56], 62.2% were female, 12.5% were caregivers, and 40.7% had at least one comorbidity (Appendix 1). The three groups differed significantly with regard to the following initial characteristics: age, being a caregiver, having been in contact with a positive case, having at least one comorbidity, fever or feeling feverish, having muscle ache, chest pain, dyspnoea, a sore throat, anosmia, agueusia, diarrhoea, and the number of systemic symptoms.

Relative to the no-COVID group, confirmed cases were significantly older and were more likely to be caregivers, to have been in contact with a confirmed case of COVID-19, and to have had anosmia or agueusia. A non-significant trend towards an association with a higher number of systemic symptoms was also observed. In contrast, chest pain and sore throat were less frequent in the “confirmed case” group.

Relative to the uncertain COVID group, confirmed cases were significantly older and were more likely to be caregiver, to have been in contact with a confirmed case of COVID-19, to have had fever or feeling feverish, muscle ache, anosmia, agueusia, diarrhoea and more than two systemic symptoms. In contrast, they were less likely to be male.

**Three-month persistent symptoms in the “confirmed COVID” and “no-COVID” groups**

Overall, the percentage of three-month persistent symptoms was higher in the confirmed COVID group than in the no-COVID group, although the difference was not statistically significant ( $P=0.090$ ) (Table 1). The confirmed COVID group was more likely to have persistent anosmia ( $OR=8.51$ ; 95% CI [1.03-70.43];  $P=0.047$ ). Similar results were found in the sensitivity analysis (Table 1).

**Predictive factors for 3-month persistent symptoms and adverse outcomes in confirmed COVID cases**

In a univariate analysis, the factors associated with 3-month persistent symptoms were fever or feeling feverish and anosmia (Table 2). In a multivariate analysis, fever and anosmia were independently associated with 3-month persistent symptoms. Similar results were found in the sensitivity analysis ( $OR_{fever}=8.49$ ; 95% CI [1.34-53.83];  $P=0.023$  and  $OR_{anosmia}=4.24$ ; 95% CI [0.99-18.23];  $P=0.052$ ).

Among the confirmed cases, we observed 16 (9.8%) COVID-19-related hospital admissions, 3 (1.8%) admissions to an intensive care unit, 13 (37.1%) referrals to an emergency department, and no deaths. In a univariate analysis, patients with 3-month adverse outcomes were older, and more likely to have at least one comorbidity (hypertension, dyslipidaemia, diabetes, and cardiovascular disease), fever or feeling feverish, and a higher number of systemic symptoms (Table 3). A trend was observed for abnormalities in a lung clinical examination. In a multivariate analysis, the composite variable “age >70 and/or at least one comorbidity”, abnormalities in a lung clinical examination and two or more systemic symptoms were independently associated with 3-month adverse outcomes (Table 3). Similar results were found in the sensitivity analysis ( $OR_{fever}=6.72$ ; 95% CI [1.24-36.54];  $P=0.027$ ;

OR<sub>≥2 systemic symptoms</sub>=44.52; 95% CI [2.67-741.89]; *P*=0,008; and OR<sub>abnormalities in a lung examination</sub>=17.58; 95% CI [1.80-171.63]; *P*=0.047).

## DISCUSSION

### Principal findings

We included 516 patients managed by GPs for suspected COVID-19 during the first wave of the disease in France: 32.2% were classified as “confirmed COVID” cases, 34.9% were classified as “no-COVID” cases, and 32.9% were classified as “uncertain COVID” cases. The clinical course was mainly benign, although the hospital admission rate (with no deaths) was 9.8% in the “confirmed COVID” group. In the latter group, the variable “age >70 and/or at least one comorbidity”, abnormalities in a lung examination, and two or more systemic symptoms were independently associated with 3-month hospital admission and referral to an emergency department. Moreover, “confirmed COVID” patients tended to have more persistent symptoms at 3 months - mainly anosmia and “other persistent symptoms”. Fever or feeling feverish, and anosmia were independently associated with the persistence of symptoms.

### Strengths and weaknesses of the study

This is one of the few studies to have included solely patients consulting in general practice; most longitudinal studies of COVID-19 patients assessed hospital-based or mixed cohorts. Moreover, our assessment of a prospective multicentre cohort recruited at different primary care health centres means that our results can be more readily extrapolated to the local or regional level. Another study strength was our comparison of “confirmed COVID”, “no-COVID” and “uncertain COVID” groups; this provided a more accurate comparison of the

initial and subsequent signs and symptoms of COVID-19. The “no COVID” group was particularly relevant for comparing the prevalence of persistent symptoms because it probably comprised patients with other viral diseases.

However, our study had some limitations. Selection bias might have been present because the RT-PCR test was only initially recommended for patients with severity criteria and/or with comorbidities, and for healthcare professionals. This may explain some of the demographic characteristics of confirmed cases. However, this bias was limited by the prescription of serology tests *a posteriori* to patients with compatible symptoms and who had not had an RT-PCR test and to patients with a negative RT-PCR test. We did not include under-18 patients and institutionalized patients. The study was limited to the greater Paris region and so might not be representative of the French population as a whole. Moreover, the groups’ size might have led to a lack of statistical power. Given the small number of patients with persistent symptoms, the corresponding results should be interpreted with caution (especially the ORs with very broad CIs). The methods for determining the presence or absence of persistent symptoms were left to the GP’s discretion; the use of particular questionnaires or scales was not imposed on them. This lack of standardization might have influenced the estimated prevalence of persistent symptoms. However, this unconstrained type of assessment was similar to that used in the GPs’ routine clinical medical practice. Lastly, COVID-19-related hospital admissions were recorded; it would have been useful to collect data on the symptom burden associated with all-cause hospital admissions.

**Comparison with other studies**

The demographic characteristics of our COVID-19 patients consulting in general practice were similar to those in the literature, particularly with regard to the mean age (43 in our

study and in Yordanov et al.'s study [22]), the proportion of caregivers [23-24], and the most prevalent comorbidities (hypertension, and diabetes) [20]. Several studies of ambulatory patients have shown that systemic symptoms (including asthenia, fever, cough, myalgia, and headaches) were frequent [4,25-27]. Anosmia and ageusia were also frequent and appeared later in the course of disease. Some experts consider that the anosmia-ageusia combination is specific for COVID-19 [12]. Digestive tract symptoms were less frequent [4,6,28-30]. Our patients also varied with regard to the signs in the GPs' clinical examination (including abnormalities in a lung examination), as found in systematic reviews [12,31]. In line with our results, most studies of outpatients have found that the course of the disease is benign and that hospital admission is not required [17,22,23]. As found in the present research, literature data have shown that a higher frequency of negative outcomes (hospital admission and death) is associated with older age [32-33] and with comorbidities like cardiovascular disease and diabetes [22,33-34]. In contrast to another study, we did not find an association with male sex [35]. However, no other studies have found that more than two systemic symptoms at the initial GP visit and abnormalities in a lung examination are predictive of an adverse outcome. These present findings and the literature data [12,31] highlight the need for a clinical consultation with the GP.

It has been widely reported that patients can experience persistent symptoms more than four weeks after an episode of COVID-19 [36]. Here, we observed a non-significant trend toward a greater prevalence of persistent symptoms at 3 months in the "confirmed COVID" group (15.7%), vs. the no-COVID group (9.6%). This finding is in line with the results of a UK study in which 13.7% of outpatients had symptoms that persisted for at least 12 weeks [36]. However, the association remained significant in our "confirmed COVID" group for anosmia and "other symptoms" (i.e. deep vein thrombosis, alopecia, palpitations, feeling feverish, and memory impairments), as also reported elsewhere [37]. A recent, large cohort study

suggested that self-reported infection was positively associated with persistent physical symptoms, whereas a positive serology test result for SARS-COV-2 was positively associated only with persistent anosmia [13]. Furthermore, it appears that one of the factors determining the presence of persistent symptoms in our COVID patients was the presence of fever during the initial GP visit. This association with fever has only previously been found in one study of elderly people [38] but not in other studies [39].

In our study, a comparison at 3 months showed that some persistent symptoms (asthenia, cough, chest pain, and dyspnoea) were not significantly more frequent in the “confirmed COVID” group - suggesting they were not specific for “long COVID-19”. Asthenia and dyspnoea were the two most common persistent symptoms in hospitalized and non-hospitalized patients [40]. However, we observed asthenia and dyspnoea respectively in around only 4% and 3% of our “confirmed COVID” patients, and with much the same frequency as in no COVID patients (4.5% and 4.5%, respectively). Outpatient studies with a control group found the presence of persistent symptoms up to 10 [41] and 12 months [42] after mild COVID-19, with miscellaneous symptoms: asthenia, headaches, smell and taste disorders, dyspnoea, memory disorders, insomnia, and difficulty concentrating [41-42]. The French health authorities also included neurological, cardiothoracic and sensory disorders in the list of persistent symptoms [43].

The results of these “long COVID-19” studies are relatively disparate and appear to show that this entity is non-specific because of the multisymptomatic, fluctuating nature of the clinical manifestations [43].

**Implications for clinicians and policymakers**

It is important to provide GPs with primary-care-specific data that enable them to optimize patient management. GPs have an essential role in combating the pandemic [44] and diagnose

most patients with COVID-19 [2]. Identifying prognostic factors and examining patients for clinical abnormalities could help to detect patients at risk, set up follow-up procedures, and anticipate possible worsening [2,45]. These strategies might be needed in France, with a view to enabling primary care to withstand future health emergencies and pandemics, as has been mentioned in Australia, New Zealand, Canada, the Netherlands, the UK, and the US [46]. The trend towards more frequent persistent symptoms in patients with COVID-19 (more specifically, anosmia and “other symptoms”) suggests that follow-up by the GP should take account of the disease’s impact on quality of life, overall health and life context via a patient-centred approach [47].

### **Unanswered questions and future research**

Our findings (notably concerning persistent symptoms) need to be confirmed in the longer term and in other patient populations (e.g. institutionalized people, children, and adolescents). Our study was partly based on electronic medical records and showed that primary care can provide important public health data. This work could be expanded with patient surveys and GP interviews, so as to combine real-time data on patients’ symptoms and adverse outcomes with patient responses to public health messaging and information on the GPs’ adaptive coping mechanisms [46].

### **CONCLUSIONS**

Cases of COVID-19 seen in primary care have an essentially benign course. However, age >70 and/or at least one comorbidity, abnormalities in a lung examination, and a higher number of systemic symptoms were associated with hospital admission and referral to an

emergency department. Our results reinforce the need for a face-to-face medical consultation by the GP to identify patients at risk of severe disease. Almost 1 in 6 COVID patients had persistent symptoms at 3 months - emphasizing the need for an overall, patient-centred approach. This frequency of persistent symptoms tended to be higher in COVID patients than in no-COVID cases. Anosmia and a group of rarer symptoms were more prevalent in the “confirmed COVID” group. Asthenia, chest pain, cough, and dyspnoea were also present in the other groups and might not be specific for a possible “long COVID-19”. Our findings in primary care need to be confirmed in prospective studies with a longer follow-up period.

**Acknowledgments:** We thank Camille Hug and Faïka Bacar for help with data collection and interpretation. We thank all the study participants and the participating health centres.

Lastly, we thank David Fraser PhD (Biotech Communication SARL, Ploudalmézeau, France) for copy-editing assistance.

**Contributors:** Each person listed as an author participated in this work in a substantive manner. Conceptualization, E.F.; methodology, E.F. and S.B.-G.; data acquisition, C.H. and F.B.; data analysis, E.B.; data interpretation, E.F., S.B.-G, and E.B., drafting and revision of the manuscript, T.-T.P, W.M., E.F. and S.B.-G. All authors have read and agreed to the published version of the manuscript.

**Funding:** This research did not receive a specific grant from any funding agency in the public, commercial or not-for-profit sectors.

**Competing interests statement:** None.

**Patient consent for publication:** Patients were not involved in the study design, conduct or reporting or the plans for dissemination.

**Data sharing statement:** Data are not publicly available, but are available from the corresponding author upon reasonable request.

**Supplementary and raw data:** The characteristics of the participating GPs and their practices are presented in Online supplement 1. Table S1. The characteristics of the study population and the univariate comparison of the three patient groups are presented in Appendix 1. The characteristics of the test results for the three groups of patients are presented in Online supplement 2. Table S2.

STROBE 2007 (v4) Statement—Checklist of items that should be included in reports of cohort studies

Section/Topic	Item #	Recommendation	Reported on page #
Title and abstract	1	(a) Indicate the study’s design with a commonly used term in the title or the abstract	1
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found	2-3
Introduction			
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	4
Objectives	3	State specific objectives, including any prespecified hypotheses	4
Methods			
Study design	4	Present key elements of study design early in the paper	5
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	5-6
Participants	6	(a) Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up	5-7
		(b) For matched studies, give matching criteria and number of exposed and unexposed	
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	6-7
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	6-7
Bias	9	Describe any efforts to address potential sources of bias	7-8
Study size	10	Explain how the study size was arrived at	5-6
Quantitative variables	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which groupings were chosen and why	7-8
Statistical methods	12	(a) Describe all statistical methods, including those used to control for confounding	7-8
		(b) Describe any methods used to examine subgroups and interactions	7-8
		(c) Explain how missing data were addressed	Tables
		(d) If applicable, explain how loss to follow-up was addressed	Figure 1
		(e) Describe any sensitivity analyses	8
Results			

Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed	9
		(b) Give reasons for non-participation at each stage	Figure 1
		(c) Consider use of a flow diagram	25
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on exposures and potential confounders	9
		(b) Indicate number of participants with missing data for each variable of interest	Tables
		(c) Summarise follow-up time (eg, average and total amount)	5
Outcome data	15*	Report numbers of outcome events or summary measures over time	
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision (eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were included	10-11
		(b) Report category boundaries when continuous variables were categorized	Tables
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time period	NA
Other analyses	17	Report other analyses done—eg analyses of subgroups and interactions, and sensitivity analyses	10-11
<b>Discussion</b>			
Key results	18	Summarise key results with reference to study objectives	11
<b>Limitations</b>			
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence	12-15
Generalisability	21	Discuss the generalisability (external validity) of the study results	14-16
<b>Other information</b>			
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the original study on which the present article is based	17

\*Give information separately for cases and controls in case-control studies and, if applicable, for exposed and unexposed groups in cohort and cross-sectional studies.

**Note:** An Explanation and Elaboration article discusses each checklist item and gives methodological background and published examples of transparent reporting. The STROBE checklist is best used in conjunction with this article (freely available on the Web sites of PLoS Medicine at <http://www.plosmedicine.org/>, Annals of Internal Medicine at <http://www.annals.org/>, and Epidemiology at <http://www.epidem.com/>). Information on the STROBE Initiative is available at [www.strobe-statement.org](http://www.strobe-statement.org).
